Feasibility of Extracting V_{td} from Radiative $B(B_S)$ DecaysD. Atwood,^{a)} B. Blok,^{b)} and A. Soni^{c)}^{a)} Stanford Linear Accelerator Center, Stanford, CA 94309^{b)} Institute for Theoretical Physics, Technion, Haifa, Israel^{c)} Brookhaven National Laboratory, Upton, NY 11973

Abstract We use existing measurements of $D^- \rightarrow K^{*0} \rho^-$ and $B \rightarrow \psi + K^*$, coupled with flavor independence of QCD, and with vector meson dominance to show that long distance contributions to $B \rightarrow \rho + \gamma$ are potentially very serious. We note that long distance (LD) contributions can be appreciably different in $B^- \rightarrow \rho^- + \gamma$ and $B^0 \rightarrow \rho^0(\omega) + \gamma$. All radiative decays of B , B_S are shown to be governed essentially by two LD and two short-distance (SD) hadronic entities. Separate measurements of $B^- \rightarrow \rho^- + \gamma$, $B^0 \rightarrow \rho^0(\omega) + \gamma$, along with $B \rightarrow K^* + \gamma$ appear necessary for a meaningful extraction of V_{td} . Measurements of $B_S \rightarrow \phi + \gamma$ and $K^{*0} + \gamma$ could also provide very useful consistency checks.

1 Introduction

The Cabibbo-Kobayashi-Maskawa (CKM) mixing angle V_{td} is a parameter of crucial importance to the Standard Model (SM) and it is still very poorly known [1]. Considerable experimental effort is directed towards its determination via the rare decay $K^+ \rightarrow \pi^+ \nu \bar{\nu}$ [2]. This process is considered to be theoretically clean for extraction of V_{td} [3]. However its branching ratio is extremely rare being about a few times 10^{-10} rendering a precise determination of V_{td} very challenging. In B -physics one well known method for determining V_{td} is via the experimentally measured B - $\bar{B}$ mixing. This requires a knowledge of the pseudoscalar decay constant f_B and the “bag parameter” B_B . Neither of these quantities is directly accessible to experiment, at least not in the near future. f_B could eventually be measured directly in B decays, say via $B \rightarrow \tau + \nu_\tau$; but this will surely take a long time. The reliability of the theoretical calculations for f_B and B_B may therefore be a cause for concern. In any case the importance of V_{td} demands that we determine it in many ways and with as much precision as possible.

One B -decay in which V_{td} enters is $B \rightarrow \rho + \gamma$ [4, 5, 6]. Since the related decay $B \rightarrow K^* + \gamma$ has already been detected [7] it is useful to understand what we may learn about V_{td} through a measurement of $B \rightarrow \rho + \gamma$. Rough estimates indicate that LD contribution to $B \rightarrow \rho + \gamma$ are potentially very serious. Since it is very difficult to accurately estimate these LD contributions a precise extraction of V_{td} from $B \rightarrow \rho + \gamma$ [8] therefore also appears rather difficult.

In this paper we try to quantify various LD and SD sources for radiative decays of all of the $B(B_S)$ meson, i.e. for:

$$B^- \rightarrow \rho^- + \gamma \tag{1}$$

$$B^0 \rightarrow \rho^0 + \gamma \tag{2}$$

$$B^0 \rightarrow \omega + \gamma \tag{3}$$

$$B^- \rightarrow K^{*-} + \gamma \tag{4} \tag{1}$$

$$B^0 \rightarrow K^{*0} + \gamma \tag{5}$$

$$B_S \rightarrow \phi + \gamma \tag{6}$$

$$B_S \rightarrow K^{*0} + \gamma \tag{7}$$

We show that two types of LD and essentially two types of SD contributions determine all of these decays. Thus separate experimental measurements of as many of these reactions as possible could allow a model independent determination of the hadronic entities and provide useful self consistency checks. Consequently, extraction of V_{td} to a meaningful level of accuracy in the long run may become possible. Clearly the necessary effort is then many times more than what is needed for a single measurement of $B \rightarrow \rho + \gamma$. On the other hand, we anticipate intense experimental activity in the area. Improvements at existing e^+e^- facilities such as CESR and LEP as well as construction of new e^+e^- based B -factories at SLAC and KEK will lead to an increased sample of B 's. Furthermore many dedicated B experiments are being proposed or planned at hadron machines. Bearing all that in mind we give a general strategy for attempting to extract V_{td} precisely from radiative B -decays.

2 A Close Look at $B \rightarrow \rho + \gamma$.

2.1 The Long Distance Contribution from $u\bar{u}$ States.

It has been known for a long time [9] that for $b \rightarrow d$ flavor-changing loop transitions (unlike for $b \rightarrow s$) the tree graphs (i.e. long-distance) become appreciably large and can easily dominate over the loop (i.e. the SD) process. A simple example is the process

$$B^- \rightarrow d\bar{u}\gamma \rightarrow \rho^- \gamma \tag{2}$$

via the non-spectator (or the annihilation) mechanism shown in Fig. 1a. Notice that this graph goes via V_{ub} , i.e. another poorly known CKM parameter. So the reaction $B \rightarrow \rho + \gamma$ can occur, in principle, even if V_{td} is vanishingly small. Although it is very difficult to accurately calculate such a contribution there are several ways of estimating its size, i.e. within a factor of two or three. We outline below two ways of calculating such contributions.

In the first method we invoke the correspondence of such annihilation graphs with spectator plus final state interactions (FSI) to note that Fig. 1(a) is exactly the same as Fig. 1(b). Fig. 1(b) shows the color allowed simple spectator contribution to $B^- \rightarrow \rho^- + \rho_V^0$ followed by $\rho_V^0 \rightarrow \gamma$ (where the subscript V stands for virtual). The first step of $B^- \rightarrow \rho^- + \rho^0$ can be estimated by normalizing with the observed analogous decay: $D^- \rightarrow \rho^- + K^{*0}$ via Fig. 1(c). This correspondence between the two decays should hold because of the flavor ($b \leftrightarrow c$) symmetry of QCD. To the extent that $m_c(m_b) \gg \Lambda_{QCD}$ the effects of QCD do not care about the flavor-label charm or bottom [10].

Also SU(3) flavor symmetry ensures that the change from K^{*0} to ρ^0 in D versus B decay is mild apart from phase-space correction. The conversion from $\rho \rightarrow \gamma$ can be dealt with by using vector-meson dominance. Thus

$$\frac{BR(B^- \rightarrow \rho^- \rho^0)}{BR(D^- \rightarrow \rho^- K^{*0})} = \left(\frac{m_b}{m_c}\right)^5 \left|\frac{V_{ub}}{V_{cs}}\right|^2 \frac{\tau_{B^+}}{\tau_{D^+}} \chi_{ps} \quad (3)$$

where χ_{ps} is the phase space ratio.

The conversion from ρ^0 to photon can be crudely estimated by using VMD to amount a multiplicative factor of about $3 * 10^{-3}$ [11, 12]. Using $\left|\frac{V_{ub}}{V_{cb}}\right| = .08, |V_{cb}| = .04$ we thus find:

$$BR(B^- \rightarrow \rho^- \gamma)_{L_u1} = 6 \times 10^{-8} \quad (4)$$

where the subscript L_u is to denote the LD contributions coming from $u\bar{u}$ state(s) such as ρ^0 .

A second method for estimating the same contribution is to use bound state method of Ref. 13 for writing down the amplitude for $B^- \rightarrow \bar{u}d\gamma$:

$$A(B^- \rightarrow \bar{u}d\gamma)_{1a} \simeq \frac{f_B}{16} e_u e \frac{g_W^2}{m_W^2} \frac{1}{m_u} V_{ub} \text{Tr} [(\not{p}_B - m_B) \not{\epsilon}_\gamma \not{q} \gamma^u P_L] \quad (5)$$

$$\bar{u}_d \gamma^u P_L v_u$$

where m_u is the constituent mass of the u quark and e_u is its charge (i.e. 2/3). Now the light-quark current can be (vacuum) saturated by the ρ^- via use of:

$$\langle 0 | \bar{u}_d \gamma_\mu \gamma_5 v_u | \rho^-(p_\rho, \epsilon_\rho) \rangle = f_\rho m_\rho \epsilon_\rho^u \quad (6)$$

where f_ρ is the decay constant of ρ i.e. about 220 MeV. Thus:

$$\frac{\Gamma(B^- \rightarrow \rho^- \gamma)_{1a}}{\Gamma(B^- \rightarrow \bar{u}d\gamma)_{1a}} \simeq 18\pi^2 \frac{f_\rho^2 m_\rho^2}{m_B^4} \left(1 - \frac{m_\rho^2}{m_B^2}\right) \simeq 7 \times 10^{-3} \quad (7)$$

Using (5) and (7) we arrive at a second estimate for the LD correction due to $\bar{u}u$ states

$$BR(B^- \rightarrow \rho^- \gamma)_{L_{u2}} \simeq 8 \times 10^{-8} \quad (8)$$

where we have used $f_B = 180$ MeV [15] and $m_u = 330$ MeV. In passing we note from eqns. 5–7 that the inclusive branching ratio for the reaction $B^- \rightarrow \bar{u}d\gamma$ via the annihilation graph is given by:

$$BR(B^- \rightarrow u\bar{d}\gamma) \approx 1.1 \times 10^{-5} \quad (9)$$

Given the intrinsic uncertainties in each of the two methods outlined above the resulting numbers in eqns. (4) and (8) should be regarded as in qualitative agreement. Thus for one class of long distance contributions, namely those due to $u\bar{u}$ states we will take the mean of the two numbers

from eqn. (4) and eqn. (8) and rather arbitrarily assign a factor of four uncertainty. Thus for the corresponding amplitude we get

$$A(B^- \rightarrow \rho^- \gamma)_{Lu} = (2 - 4) \times 10^{-4} \quad (10)$$

Now let us address the case of the neutral B i.e. the corresponding LD contributions from $\bar{u}u$ states to $(B^0 \rightarrow \rho^0 \gamma)$. Then Fig. 1(a) gets redrawn as Fig. 1(d) and Fig. 1(b) gets redrawn as Fig. 1(e). In each case we see that the graphs for B^0 are color suppressed. Thus

$$A(B^0 \rightarrow \rho^0 \gamma)_{Lu} = - \left(\frac{1}{3} \times \frac{3}{2} \times \frac{1}{\sqrt{2}} \right) \times (2 - 4) \times 10^{-4} \quad (11)$$

$$A(B^0 \rightarrow \omega \gamma)_{Lu} = \frac{1}{6\sqrt{2}} (2 - 4) \times 10^{-4} \quad (12)$$

2.2 The Long Distance Contributions from $c\bar{c}$ States.

We next turn our attention to the LD contributions to $B^- \rightarrow \rho^- + \gamma$ from $c\bar{c}$ states. The most notable origin is the chain $B^- \rightarrow \rho^- + \psi_V$ followed by $\psi_V \rightarrow \gamma$. Using the measured rate

$$BR(B^0 \rightarrow K^{*0} \psi) = (1.6 \pm .3) \times 10^{-3} \quad (13)$$

we immediately get

$$BR(B^- \rightarrow \rho^- \psi) = 2BR(B^0 \rightarrow \rho^0 \psi) = \lambda^2 BR(B^0 \rightarrow K^{*0} \psi) p_{sK^*\rho} \quad (14)$$

where $\lambda \equiv \sin \theta_c = .22$ and $p_{sK^*\rho}$ is a phase space correction factor estimated to be about 1.4 due to the mass difference between ρ and K^* [16]. Following Ref. 11 conversion factor from $\psi \rightarrow \gamma$ is estimated at 5×10^{-3} . However, in this $\psi \rightarrow \gamma$ conversion we want to include only the transversely polarized fraction of ψ 's. These are estimated to be about 30% [17]. Thus, for the amplitude of LD contributions from $c\bar{c}$ states we get

$$A(B^- \rightarrow \rho^- \gamma)_{L_c} = (2 - 6) \times 10^{-4} \quad (15)$$

where in specifying the range we are again estimating about a factor of two uncertainty (in the amplitude).

2.3 The Short-Distance Contributions to $B \rightarrow \rho + \gamma$

The SD (or penguin) contributions arise from loop graphs, such as Fig. 1(f) and 1(g). It is known for a long time that QCD corrections play an important role here. We recall that this is due to the fact that in the pure electroweak penguin (Fig. 1(f)) there is an accidental cancellation of the coefficients of terms that maintain GIM unitarity with a logarithmic dependence on the internal quark mass (i.e. m_u, m_c, m_t). As a result the leading terms exhibit a power law dependence on that mass. On switching on QCD the coefficient of the log term becomes nonvanishing and results in enhanced QCD radiative effects.

By now there is an extensive literature describing the effects of QCD on radiative decays of B 's. For our purpose it is useful to first discuss the $b \rightarrow s$ process namely the one relevant to $B^-(B^0) \rightarrow K^{*-}(K^{*0}) + \gamma$ (or to $B_S \rightarrow \phi + \gamma$). Recall the CKM unitarity for this channel:

$$v_u^q + v_c^q + v_t^q = 0 \quad (16)$$

where $v_j^q = V_{jb}V_{jq}^*$, $j = u, c, t$ and $q = s$ or d . Recall also that [1]

$$V_{us} = \lambda \simeq .22 \quad (17)$$

$$\frac{V_{ub}}{V_{cb}} = .08 \pm .03 \quad (18)$$

$$V_{tb} = .99 \pm .01 \quad (19)$$

Thus for $b \rightarrow s$ case the up quark term ($V_{ub}V_{us}^*$) is negligible in comparison

to the other two terms in eqn. (16). This has two important consequences. First is that one gets the usual relation:

$$V_{ts} \simeq -V_{cb} \quad (20)$$

to a very good approximation. The second important consequence of the smallness of $V_{ub}V_{us}^*$ is that in the $b \rightarrow s$ penguin loop the u quark contribution is forced to become so small that the precise dependence on m_u is not at all important. Such is not the case for $b \rightarrow d$ penguins as we will soon elaborate.

The penguin (SD) contributions can be written as

$$A_p^q = \sum_j f_j v_j^q \quad (21)$$

For $q = s$, we can use eqn. (16) and rewrite

$$A_p^s = (f_t - f_c)v_t^s + (f_u - f_c)v_u^s \quad (22)$$

Since v_u^s is extremely small the second term is bound to make a negligibly small contribution and consequently the assumption that $f_c = f_u$ that one usually makes [18] becomes a very safe assumption. Then for $b \rightarrow s$ with a very good approximation one gets

$$A_p^s = (f_t - f_c)v_t^s \equiv (f_t - f_c)V_{ts} \quad (23)$$

For the case of $b \rightarrow d$ transitions the u quark in the loop no longer appears with the small parameter $V_{us}(\equiv \lambda)$ multiplying its effects and the charm and the top quark both now have smaller CKM factors monitoring their contributions to the penguin amplitude. The u quark contribution is no longer necessarily negligible in comparison to the others and the assumption $f_c = f_u$ is no longer a good approximation since it forces a potentially important (u quark) contribution to unnaturally vanish. Any reasonable deviation of f_c/f_u away from unity would have important corrections. To make the best use of

the experimental information that one gets from measurement of $B \rightarrow K^* \gamma$, it is prudent now to use unitarity and rewrite the $b \rightarrow d$ penguin as:

$$A_p^d = (f_t - f_c)v_t^d + (f_u - f_c)v_u^d \quad (24)$$

Taking ratios of equations (23) and (24):

$$\begin{aligned} A_p^d/A_p^s &= \frac{V_{td}}{V_{ts}}[1 + \Delta] \\ \Delta &\equiv \left(\frac{f_u - f_c}{f_t - f_c}\right) \left(\frac{V_{ub}}{V_{td}}\right) \end{aligned} \quad (25)$$

Thus there are two hadronic entities:

$$f_u - f_c \equiv S_{uc} \quad (26)$$

$$f_t - f_c \equiv S_{tc} \quad (27)$$

monitoring all the SD contributions in $b \rightarrow s$ and $b \rightarrow d$ penguins. f_t and f_c have recently been calculated in Ref. [18]:

$$f_t \simeq -.11 \quad (28)$$

$$f_c \simeq .16 \quad (29)$$

giving

$$S_{tc} = -.27 \quad (30)$$

For extraction of V_{td} from experiment the deviation from unity of the quantity in square parenthesis in equation (25) is important. First let us estimate the CKM ratio that enters there. We note that the use of [15]

$$f_B = 180 \pm 40 \text{ MeV} \quad (31)$$

$$B_B = 1 \pm .2 \quad (32)$$

emerging from lattice calculations along with the measured B - $\bar{B}$ mixing gives

$$\frac{V_{td}}{V_{ts}} \simeq 0.22 \pm .08 \quad (33)$$

Thus using (as 90% CL bounds)

$$|V_{ub}/V_{cb}| < .13 \quad (34)$$

$$|V_{td}/V_{ts}| \geq .09 \quad (35)$$

we get

$$|V_{ub}/V_{td}| \lesssim 1.5 \quad (36)$$

A precise value for $f_u - f_c$ is extremely difficult to calculate. We will assume that f_u and f_c depend logarithmically on m_u and m_c . Using constituent masses $m_u \simeq 0.3$ GeV, $m_c \simeq 1.8$ GeV and the numerical result (29) of Ref. [18] we then *crudely estimate*:

$$S_{uc}/S_{tc} = -.30 \quad (37)$$

Thus the ratio of the SD amplitudes for $b \rightarrow d$ and $b \rightarrow s$ may deviate appreciably from the CKM ratio V_{td}/V_{ts} . We note this deviation from the simple CKM scaling is controlled crucially by the ratio V_{ub}/V_{td} just as the relative importance of the LD contributions due to $u\bar{u}$ states (i.e L_u) to $B \rightarrow \rho + \gamma$ is controlled by V_{ub}/V_{td} . If the mild indications from the current central values of V_{ub}/V_{cb} and V_{td}/V_{ts} (.08 versus .22) is confirmed then the extraction of V_{td} from $B \rightarrow \rho + \gamma$ will indeed be easier than otherwise.

To gauge the relative importance of the LD and the SD contributions to $(B \rightarrow \rho + \gamma)$ we need to estimate A_p^s (i.e. SD amplitude for $b \rightarrow s$) so as to be able to use eqn. (25) to get A_p^d (i.e. the SD amplitude for $b \rightarrow d$). We can try to use the experimental result on $B \rightarrow K^* + \gamma$ for that purpose; so we turn our attention to that reaction now.

2.4 The Long- and Short Distance Contributions to $B \rightarrow K^* + \gamma$

The LD contribution from $\bar{u}u$ states is easily estimated from eqn. (10)

$$A^s(B^- \rightarrow K^{*-}\gamma)_{L_u} \simeq (4 - 8) \times 10^{-5} \quad (38)$$

$$A^s(B^0 \rightarrow K^{*0}\gamma)_{L_u} \simeq (2 - 4) \times 10^{-5} \quad (39)$$

Similarly, from eqn. (13), with use of the $\psi \rightarrow \gamma$ conversion factor of 5×10^{-3} and incorporating a factor of 0.3 for the fraction of transversely polarized ψ 's we get

$$A(B \rightarrow K^* + \gamma)_{L_c} = (1 - 3) \times 10^{-3} \quad (40)$$

So for $B \rightarrow K^*\gamma$ the LD contributions due to $c\bar{c}$ completely dominate over the $u\bar{u}$ ones [19].

Recall now the recent experimental result [7]

$$BR(B \rightarrow K^*\gamma) = (4.5 \pm 1.5 \pm 0.9) \times 10^{-5} \quad (41)$$

For the amplitude we translate this as

$$A(B \rightarrow K^*\gamma) |_{\text{expt}} \simeq (6.7 \pm 1.7) \times 10^{-3} \quad (42)$$

From equations (40) and (42) we see that there can be about 15–50% LD contributions in the observed experimental result. Combining those two equations we arrive at the SD component

$$A_p^s \equiv A(B \rightarrow K^* + \gamma)_{SD} = (4.7 \pm 2.7) \times 10^{-3} \quad (43)$$

In arriving at eqn. (43) we have made a strong assumption that the SD and LD ($c\bar{c}$) amplitudes for $B \rightarrow K^* + \gamma$ have the same relative sign. This

assumption is based on the belief that an opposite choice of signs would make the exclusive to inclusive ratio for the short distance component alone, i.e.

$$H_{K^*} = \frac{\Gamma(B \rightarrow K^* + \gamma)}{\Gamma(b \rightarrow s + \gamma)} \quad (44)$$

become uncomfortably large. The point is that lattice methods have been used to calculate this hadronization ratio for the single operator

$$\bar{s}_L \sigma_{\mu\nu} b_R F^{\mu\nu} \quad (45)$$

that emerges from the short distance expansion. The results of the lattice calculation are [20]:

$$H_{K^*} = 6.0 \pm 1.2 \pm 3.4\% \quad (46)$$

For our purpose we will adopt a very conservative interpretation of the lattice results, namely

$$H_{K^*} < 12\% \quad (47)$$

Recall now the recent CLEO result [21]:

$$BR(b \rightarrow \gamma + s) = (2.32 \pm .51 \pm .29 \pm .32) \times 10^{-4} \quad (48)$$

Combining equations (41) and (48) indicates that the experimental value of the exclusive to inclusive ratio is around 20% which tends to be on the high side compared to the lattice expectation. By attributing a fraction of the observed exclusive signal to come from LD sources as in equation (43) brings the hadronization ratio for the SD piece i.e.

$$\frac{(4.7 \times 10^{-3})^2}{2.3 \times 10^{-4}} \sim 9.6\% \quad (49)$$

to be more in the ball park of the lattice results. If, on the other hand, we take the LD and SD contributions to $B \rightarrow K^* \gamma$ to have a relative negative sign then the SD fraction would have to be

$$\frac{(8.7 \times 10^{-3})^2}{2.3 \times 10^{-4}} \sim 33\%$$

which is too large from the lattice perspective.

2.5 Estimates for the Relative Importance of LD Contribution to $B \rightarrow \rho + \gamma$

Using eqn. (25) and (43) and invoking SU(3) gives us the SD contribution to $(B \rightarrow \rho + \gamma)$

$$A(B \rightarrow \rho + \gamma)_{SD} = \frac{V_{td}}{V_{ts}} [1 + \Delta] \times (4.7 \pm 2.7) \times 10^{-3} \quad (50)$$

$$\sim (5 - 15) \times 10^{-4} \quad (51)$$

From eqn. (15) and (51) we see that for $B^- \rightarrow \rho^- + \gamma$ the LD $c\bar{c}$ states are at least 15% of (and could even dominate over) the SD ones. Indeed even that minimum value of 15% implies a contamination of these LD effects on the rate for $B^- \rightarrow \rho^- \gamma$ to approach 30%. From eqn. (10) we see that the $u\bar{u}$ states seem to be somewhat less important than the $c\bar{c}$ but are roughly comparable. We emphasize again that the numbers given for L_u in eqn. 10 assume $\left| \frac{V_{ub}}{V_{cb}} \right| = .08$. Given the intrinsic difficulties of the LD estimates it appears doubtful that $B^- \rightarrow \rho^- + \gamma$ alone in conjunction with $B \rightarrow K^* + \gamma$ can be used to deduce reliable information on V_{td} before a lot more experimental data on radiative decays becomes available. In this regard a precise value of V_{ub} as well as the relative sign of $V_{ub}V_{ud}^*$ with $V_{cb}V_{cd}^*$ is very important since a relative negative sign between these two CKM elements would result in (at least) a partial cancellation of the long distance L_u and L_c terms.

The LD contribution to $B^0 \rightarrow \rho^0 + \gamma$ from $u\bar{u}$ states are substantially less (see eqn. (11)) than for $B^- \rightarrow \rho^- + \gamma$. The SD contributions are the

same for B^0 and B^- (i.e. eqns. (50) and (51)). Thus $B^0 \rightarrow \rho^0 + \gamma$ may have appreciable advantages over $B^- \rightarrow \rho^- + \gamma$ for learning about V_{td} . In any event, it seems clear from the preceding estimates that the rates for $B^- \rightarrow \rho + \gamma$ may be quite different from that of $B^0 \rightarrow \rho + \gamma$. Since the SD contributions (which scale with V_{td}) are the same for B^- and B^0 and the LD ones are not, separate measurements of B^- and B^0 radiative decays are important to understanding the dynamics of these decays and they are essential for facilitating any reliable determination of V_{td} .

3 Four Hadronic Entities Essentially Determine all the Radiative B -Decays.

In the preceding section we have discussed the long and short distance contributions to charged and neutral B decays to $\rho + \gamma$ and $K^* + \gamma$. During the course of that discussion we had to introduce two LD (namely L_u and L_c) and two short distance (namely S_{tc} and S_{uc}) entities. Indeed all the radiative B , B_S decays to the seven final states given in eqn. (1) are governed by the same four hadronic entities [22]. Of course the dependence on CKM angles are not the same (also there are obvious differences in N_c dependence and on flavor SU(3)) that have to be taken into account. Thus we can write

$$A(B^- \rightarrow \rho^- + \gamma) = e_u \left[(N_C - 1) v_u^d L_u + v_c^d L_c + k_b c_{B\rho} T_{1_{B\rho}} (v_t^d S_{tc} + v_u^d S_{uc}) \right] \quad (52)$$

$$A(B^0 \rightarrow \rho^0 + \gamma) = -\frac{1}{\sqrt{2}} \left[(e_u - e_d) v_u^d L_u + e_u v_c^d L_c + k_b c_{B\rho} T_{1_{B\rho}} (v_t^d S_{tc} + v_u^d S_{uc}) \right] \quad (53)$$

Also

$$A(B^0 \rightarrow \omega + \gamma) = \frac{1}{\sqrt{2}} \left[(e_u + e_d) v_u^d L_u + e_u v_c^d L_c + k_b c_{B\rho} T_{1_{B\rho}} (v_t^d S_{tc} + v_u^d S_{uc}) \right] \quad (54)$$

$$\begin{aligned}
A(B^- \rightarrow K^{*-} + \gamma) &= e_u [v_u^s N_c L_u + v_c^s L_c + k_b c_{BK^*} T_{1_{BK^*}} (v_t^s S_{tc} + v_u^s S_{uc})] + \\
&\simeq e_u [v_c^s L_c + k_b c_{BK^*} T_{1_{BK^*}} v_t^s S_{tc}] \quad (55)
\end{aligned}$$

$$\begin{aligned}
A(B^0 \rightarrow K^{*0} + \gamma) &= e_u [v_u^s L_u + v_c^s L_c + k_b c_{BK^*} T_{1_{BK^*}} (v_t^s S_{tc} + v_u^s S_{uc})] \\
&\simeq e_u [v_c^s L_c + k_b c_{BK^*} T_{1_{BK^*}} v_t^s S_{tc}] \quad (56)
\end{aligned}$$

Similarly for related decays of B_S :

$$\begin{aligned}
A(B_S \rightarrow \phi + \gamma) &= e_u [v_u^s L_u + v_c^s L_c + k_b c_{B_s \phi} T_{1_{B_s \phi}} (v_t^s S_{tc} + v_u^s S_{uc})] \\
&\simeq e_u [v_c^s L_c + k_b c_{B_s \phi} T_{1_{B_s \phi}} v_t^s S_{tc}] \quad (57)
\end{aligned}$$

$$A(B_S \rightarrow K^* + \gamma) = e_u [v_u^d L_u + v_c^d L_c + k_b c_{B_s K^*} T_{1_{B_s K^*}} (v_t^d S_{tc} + v_u^d S_{uc})] \quad (58)$$

Here k_b is a normalization constant designed so that the width for the flavor-changing transition coming from the short distance piece alone is related properly to the factors S_{tc} and S_{uc} . Thus

$$\Gamma(b \rightarrow d\gamma)_{SD} \equiv \Gamma(b \rightarrow d\gamma)_{\text{penguin}} = [e_u k_b (v_t^d S_{tc} + v_u^d S_{uc})]^2 \quad (59)$$

T_1 is the only form factor (at $q^2 = 0$) that determines the exclusive to inclusive ratio from the short-distance penguin part [19]. Thus

$$\frac{\Gamma(B \rightarrow \gamma \rho)_{SD}}{\Gamma(b \rightarrow \gamma d)_{SD}} = c_{B\rho}^2 T_{1B\rho}^2 \quad (60)$$

where

$$C_{B\rho}^2 = 4 \left(\frac{m_B}{m_b} \right)^3 \left[1 - \frac{m_\rho^2}{m_B^2} \right]^3 \quad (61)$$

4 Discussion

In Table 1 we give rough estimates for the radiative modes. For simplicity we have assumed that $T_1(q^2 = 0)$ is the same for $B \rightarrow K^*, \rho$ and $B_s \rightarrow K^*, \phi$.

Table 1: Numerical Estimates

Reaction	Amplitudes /10 ⁻⁴			Branching Ratio/10 ⁻⁷	
	($u\bar{u}$) _{LD}	($c\bar{c}$) _{LD}	SD	SD only	Total
$B^+ \rightarrow \rho^+ \gamma$	3 ± 1	4 ± 2	10 ± 6	2–25	.4–68
$B^0 \rightarrow \rho^0 \gamma$	$1.1 \pm .4$	2.8 ± 1.4	7 ± 4	1–12	1–32
$B^0 \rightarrow \omega^0 \gamma$	$.2 \pm .1$	2.8 ± 1.4	7 ± 4	1–12	2–23
$B \rightarrow K^* \gamma$	$.6 \pm .3$	20 ± 10	50 ± 30	40–640	90–1200
$B_S \rightarrow K^* \gamma$	$1.5 \pm .5$	4 ± 2	10 ± 6	2–26	2–58
$B_S \rightarrow \phi \gamma$	$.6 \pm .2$	20 ± 10	50 ± 30	40–640	90–1200

There could easily be differences between these form factors amounting to 10 or even 20%. Future lattice and QCD sum rule calculations should be able to determine these quite reliably.

Notice that the spread in the range due to the SD piece alone is less than the spread after the LD contributions are included. This is in part because the relative signs are not known at this time. Thus typically the SD piece alone has a range of about one order of magnitude and that increases appreciably to the extent that in one case it becomes as much as two orders of magnitude when the LD pieces are also included.

We must also emphasize that the entries in the table are highly correlated so that as better experimental information on any mode(s) becomes available then it will effect the estimates for all of the modes. This is of course another way of saying that all of the decays involve only a few (i.e. four) hadronic quantities. In the case of $B \rightarrow K^* \gamma$ the recently obtained experimental measurement has been used to fix the relative sign between the SD piece and the LD ($c\bar{c}$) piece. There still remains an uncertainty in the theoretical expectation for the total BR of about one order of magnitude. Measurements of $B \rightarrow \rho(\omega) + \gamma$, especially separate ones for charged and neutral, will significantly aid such an analysis in the future. Differences in the BR s for

$\rho^- + \gamma$, $\rho^0 + \gamma$ and $\omega + \gamma$ would be an excellent indicator of the extent of the LD contamination. If the LD contributions are small then the BR s for these modes should follow the expected factor of two difference due to the difference in their naive quark content.

Indeed from eqns. (52–54) one finds:

$$|A(B^- \rightarrow \rho^- + \gamma)| - \sqrt{2}|A(B^0 \rightarrow \rho^0 + \gamma)| = V_u^d L_u [3e_u - e_d] \quad (62)$$

$$|A(B^- \rightarrow \rho^- + \gamma)| - \sqrt{2}|A(B^0 \rightarrow \omega + \gamma)| = V_u^d L_u [3e_u + e_d]. \quad (63)$$

Thus experimental determination of the differences in the BR 's can be used to quantitatively deduce the long distance piece due to $u\bar{u}$.

Lattice calculations of $B \rightarrow K^* + \gamma$ could also play a very useful role. If improved lattice calculations for $B \rightarrow K^* \gamma$ also do not agree in their determination of the ratio $H_{K^*} \equiv [BR(B \rightarrow K^* + \gamma)/BR(b \rightarrow s + \gamma)]$ with improved experimental measurements then the difference between the two must be attributed to long distance pieces (presumably due to $c\bar{c}$ states) that the lattice calculations do not include.
